Installation and building

1.1 Dependencies

Spud and Diamond depend on the following packages:

- Fortran, C and C++ compilers
- Python (http://python.org/)
- Python setuptools (http://peak.telecommunity.com/DevCenter/setuptools)
- PyGTK (http://www.pygtk.org/)
- lxml (http://codespeak.net/lxml/)
- Trang (http://www.thaiopensource.com/relaxng/trang.html)
- libxml2 (http://xmlsoft.org/)
- LaTeX (for the manual) (http://www.latex-project.org/)

Users of Ubuntu should be able to install all the needed dependencies by adding the repository listed below and typing:

```
sudo apt-get update
dsudo apt-get build-dep spud
```

1.2 Obtaining the source

Spud source code is held in a bzr repository. The current development version is available via:

```
bzr co lp:spud
```

1.3 Building from source

Spud is built using a standard autoconf system. It should be possible to build spud and install it in `/usr/local` simply by typing:
./configure
make
make install

Installing to an alternative location is possible by specifying the --prefix option to configure. For a full list of configure options type:

./configure --help

1.4 Ubuntu packages

Ubuntu packages are available from a Launchpad repository managed by the Applied Modelling and Computation Group at Imperial College London. To add this repository to your system sources, run:

sudo apt-add-repository ppa:amcg/ppa

The Spud library and the base language are installed by the libspud-dev package while diamond is shipped in the diamond package. Both packages are built from the spud source package. Binary packages are supplied for the i386 and amd64 architectures. After adding the repository, install the packages by typing:

sudo apt-get update
sudo apt-get install diamond libspud-dev
Chapter 2

Schemas and the Spud base language

The World Wide Web Consortium’s Extensible Markup Language (XML) provides a generic syntax for machine parseable languages. These allow the organisation of model input options into a tree of nested elements. Utilising such a structure within the options file allows distinct groups of options to be gathered together in branches while suboption dependencies can be represented as child elements.

2.1 RELAX NG

Spud uses the RELAX NG schema language within the XML system. For full documentation of RELAX NG see http://relaxng.org/. The compact syntax tutorial is particularly useful.

The examples presented here are shown in a compact syntax of RELAX NG. This is the preferred syntax for editing Spud schemas and the format it is shipped in. However the more verbose XML syntax is better supported by software parsers. Hence the completed schema, including the base language, is translated from compact to XML syntax using the software package Trang before use by Spud based tools like Diamond.

2.2 Base language named patterns

The RELAX NG language allows different schemas to be imported into one another, which enables Spud to define a base language for schema developers. The Spud base language thus provides core schema objects (known in RELAX NG as patterns) that enable generic tools included in Spud to handle low level data in an elegant manner.

For example the real_dim_symmetric_tensor pattern is defined below:

```relaxng
# A dim x dim real matrix (rank 2 tensor) constrained to be symmetric.
real_dim_symmetric_tensor =
{
  element real_value{
    attribute symmetric {"true"},
    attribute rank { "2" },
    # Setting dim1, dim2 to a function of dim allows the gui
    # to set the tensor to the right shape.
    attribute dim1 { "dim" },
    attribute dim2 { "dim" },
    attribute shape { list{xsd:integer, xsd:integer} },
    list {xsd:float+}
  },
  comment

```
This core object contains all the information required to define the properties of a real, symmetric, rank 2 tensor with square dimensions equal to the physical dimension specified. This enables Spud based generic tools to reduce the level of information required as input from the user. In this case the user is only required to provide a list of reals to fill out the tensor while the generic tool will ensure it is symmetric, ordered correctly and save the rank, shape and dimensions. Thus from the developers perspective all the information required to import a symmetric tensor is available from Spud alongside the user’s input.

As can be seen above the principal element of the `real_dim_symmetric_tensor` pattern is `real_value`. Modification of the rank, shape and dimension attributes of this element allows the Spud based language to be expanded easily to incorporate other real data structures. For instance, a rank 1 real vector with length equal to the physical dimension specified is defined in the `real_dim_vector` pattern:

```plaintext
# A real vector of length dim
real_dim_vector =
{
    element real_value{
        attribute rank { "1" },
        # Setting dim1 to a function of dim allows the gui to set the
        # vector to the right length.
        attribute dim1 { "dim" },
        attribute shape { xsd:integer },
        list{xsd:float+}
    },
    comment
}
```

Similar extensions can be made for an integer based `integer_value` element, while a `string_value` element allows the definition of several character patterns known to Spud generic tools (such as the `comment` pattern seen in the examples above). This allows for the definition of the full Spud base language as follows:

- `comment`: A string value that allows users to annotate their input throughout the XML tree structure. Included in all Spud base language patterns.
- `anystring`: A string value for the input of any generic character string required in the options tree. Suggests a display of 1 line within Spud based tools such as Diamond.
- `filename`: A string value for the input of filenames in the options tree. Allows the use of a file selector and suggests a display of 1 line within Spud based tools such as Diamond.
- `Python_code`: A string value for the input of Python code into the options tree. Suggests a display of 20 lines within Spud based tools such as Diamond.
- `integer`: An integer value of rank 0 and length 1.
- `integer_vector`: A rank 1 vector of integers of arbitrary length. Spud tools record the shape of the input.
- `integer_tensor`: A tensor of integers of arbitrary dimensions. Spud tools record the shape of the input.
- `integer_dim_vector`: A rank 1 vector of integers with length equal to the physical dimension specified.
2.2. BASE LANGUAGE NAMED PATTERNS

integer_dim_minus_one_vector
A rank 1 vector of integers with length equal to 1 less than the physical dimension specified.

integer_dim_tensor
A rank 2 tensor of integers with square dimensions equal to the physical dimension specified.

integer_dim_symmetric_tensor
A rank 2 symmetric tensor of integers with square dimensions equal to the physical dimension specified.

integer_dim_minus_one_tensor
A rank 2 tensor of integers with square dimensions equal to 1 less than the physical dimension specified.

integer_dim_minus_one_symmetric_tensor
A rank 2 symmetric tensor of integers with square dimensions equal to 1 less than the physical dimension specified.

real
A real value of rank 0 and length 1.

real_vector
A rank 1 vector of reals of arbitrary length. Spud tools record the shape of the input.

real_tensor
A rank 2 tensor of reals of arbitrary dimensions. Spud tools record the shape of the input.

real_dim_vector
A rank 1 vector of reals with length equal to the physical dimension specified.

real_dim_minus_one_vector
A rank 1 vector of reals with length equal to 1 less than the physical dimension specified.

real_dim_tensor
A rank 2 tensor of reals with square dimensions equal to the physical dimension specified.

real_dim_symmetric_tensor
A rank 2 tensor of reals with square dimensions equal to the physical dimension specified.

real_dim_minus_one_tensor
A rank 2 tensor of reals with square dimensions equal to 1 less than the physical dimension specified.

real_dim_minus_one_symmetric_tensor
A rank 2 tensor of reals with square dimensions equal to 1 less than the physical dimension specified.

2.2.1 Including the base language in the schema

The base language is described in the file spud_base.rnc. This file is installed in @prefix@/share/spud, where the default value of @prefix@ is /usr. It may be referenced without prefixing the path. The top line of every spud schema should read

include "spud_base.rnc"

2.2.2 The real_value and integer_value elements

As mentioned above, the real_value and integer_value elements are the low-level implementations of the real and integer named patterns in the base language. The full schema syntax of these elements is illustrated by the definition of the real_dim_minus_one_tensor pattern in the base language:

# A dim-1 x dim-1 real matrix (rank 2 tensor).
real_dim_minus_one_tensor =
{
  element real_value{
    attribute symmetric {"false"},
}
attribute rank { "2" },
# Setting dim1, dim2 to a function of dim allows the gui to set the
tensor to the right shape.
attribute dim1 { "dim-1" },
attribute dim2 { "dim-1" },
attribute shape { list{xsd:integer, xsd:integer} },
list {xsd:float+}
),
comment
)

The symmetric and dim2 attributes are only present if rank is 2 while the dim1 and shape attributes are only present where rank is at least 1. If rank is equal to 1 then shape will be a single xsd:integer rather than a list of 2. The dim1 and dim2 attributes are Python expressions of the variable dim.

2.2.3 The string_value element

Customised string values, such as fixed strings or multiline strings, are constructed using the string_value element. This element wraps a string and a lines attribute. The lines attribute does not enforce a length on the string but is rather a hint to the user interface as to the size of string box which would be appropriate. The schema syntax of the string_value element is illustrated by the definition of the main anystring pattern from the base language:

# A simple string
anystring =
{
    element string_value{
        # Lines is a hint to the gui about the size of the text box.
        # It is not an enforced limit on string length.
        attribute lines { "1" },
        xsd:string
    },
    comment
}

An example of a customised string is this choice of two available string values:

## Format for dump files. Choose from fluidity dumpfile or vtk.

element dump_format {
    element string_value{
        "fluidity_dumpfile"|"vtk"
    }
}

2.2.4 Symmetric tensors

Some of the Spud base language patterns refer to symmetric tensors. In every case, the full tensor is stored and retrieving the tensor using libspud. It is the responsibility of Spud user interface tools such as Diamond to enforce the symmetry of tensors input by the user.
2.3 SPECIFYING PROBLEM DIMENSION

The dimension of the problem affects how all of the dimension-specific named patterns in the schema are handled. It is specified by having an integer-valued `dimension` element as a child of the `geometry` element which is in turn a child of the root element. Spud schemas are required to define `dimension` and `geometry` elements if they make use of any of the named patterns whose name includes the string `dim`. Figure 2.1 illustrates a trivial Spud schema in which the dimension attribute is given using a customised `integer_value` element which only permits the values 2 or 3 to be given.

2.4 Restrictions on the base language

In order to facilitate processing of schemas by libspud and Diamond, and in particular to make the presentation of a simple and intuitive user interface possible, several restrictions are imposed on RELAX NG schemas used in Spud.

- Choice nodes must be choices between single elements (e.g. a choice between a OR (b AND c) is invalid).
- Elements with the same tag under the same parent are allowed. However, at most one can be + (oneOrMore) or * (zeroOrMore). Elements with the same tag under the same parent must each
have a name attribute with a unique value.

- **name** attributes may contain only alpha-numeric characters, or characters in the set "/_:[]"
- Recursive schema elements are not supported.

2.5 Comments and annotations

There are three layers of comment which are applicable in Spud. The schema, as with any piece of source code, can contain comments which are of use to other developers editing the schema. Second, the schema can embed documentation for the problem description language. This documentation will be displayed to the model user by Diamond. The former comments are known as schema comments and are written with a single leading hash (#) while the latter are known as schema annotations and are written with a double leading hash (##). Schema annotations must be written immediately before the element they document.

Finally, the **comment** named pattern will cause diamond to associate a user comment box with the parent element. This enables users to document their problem description files. Each of the named patterns in the base language also includes the **comment** pattern so that every parameter in an input file can have a user comment associated with it. Figure 2.1 shows a simple schema incorporating all three layers of comment.

2.6 Preprocessing the schema for use with Diamond

RELAX NG comes in two equivalent formats: XML syntax (with file suffix .rng) and compact syntax (with file suffix .rnc). Compact syntax is optimised for human use, while XML syntax is optimised for ease of machine parsing. Therefore, it is recommended that model developers write the schema in compact syntax, then transform it using a supplied tool to XML syntax for use with Diamond and other validation tools. To transform compact syntax into XML syntax, use the command:

```
spud-preprocess /path/to/schema.rnc
```

This will create a file called schema.rng in the same directory.
Chapter 3

Libspud

Libspud provides C, C++ and Fortran interfaces for accessing the options specified in a Spud XML file.

3.1 The options tree

Spud XML files are read into an in-memory tree structure which reflects the tree of nested elements in the XML. Nodes in this tree are indexed by strings, i.e. the options tree is a dictionary in which values are interrogated via keys.

3.2 Option key syntax

The option key syntax is similar to Unix file path syntax. Consider the simple example, simple.xml, which is valid with respect to the schema in figure 2.1:

```xml
<model_options>
  <simulation_name>
    <string_value lines="1">Basic simulation</string_value>
  </simulation_name>
  <geometry>
    <dimension>
      <integer_value rank="0">3</integer_value>
    </dimension>
  </geometry>
</model_options>
```

The simulation name and the dimension of the geometry may be accessed using the following Fortran program:

```fortran
program fetch_info
  use spud
  implicit none

  integer :: dimension
  character(len=255) :: simulation_name

  call load_options("simple.xml")
  call get_option("/simulation_name", simulation_name)
```

15
call get_option("/geometry/dimension", dimension)
end program fetch_info

The option key /simulation_name accesses the element called simulation_name that is a child of the root element (which in this case is called model_options). The option key /geometry/dimension accesses the element dimension which in turn is a child of the root element.

3.2.1 Multiple elements

One of the restrictions that Spud places on RELAX NG schemas is that each element of the same name under the same parent must be differentiated by a name attribute. An example will clarify what is valid. Consider the file complex_invalid.xml:

```
<model_options>
  <simulation_name>
    <string_value lines="1">Basic simulation</string_value>
  </simulation_name>
  <geometry>
    <dimension>
      <integer_value rank="0">3</integer_value>
    </dimension>
    <mesh>
      <string_value type="filename" lines="1">mesh_A.msh</string_value>
    </mesh>
    <mesh>
      <string_value type="filename" lines="1">mesh_B.msh</string_value>
    </mesh>
  </geometry>
</model_options>
```

This file is invalid as there are two mesh elements beneath the same geometry element, and they are not differentiated by a unique name attribute. To make this file valid we must differentiate the two mesh elements by adding a name attribute:

```
<model_options>
  <simulation_name>
    <string_value lines="1">Basic simulation</string_value>
  </simulation_name>
  <geometry>
    <dimension>
      <integer_value rank="0">3</integer_value>
    </dimension>
    <mesh name="PositionMesh">
      <string_value type="filename" lines="1">mesh_A.msh</string_value>
    </mesh>
    <mesh name="VelocityMesh">
      <string_value type="filename" lines="1">mesh_B.msh</string_value>
    </mesh>
  </geometry>
</model_options>
```

This file is now valid as the two mesh elements have different name values.

To access these elements in the model, the option keys
3.3. LANGUAGE SPECIFIC FEATURES

/geometry/mesh[0]  
/geometry/mesh[1]  

may be used to access the elements in order, or they may be accessed by name by

/geometry/mesh::PositionMesh  
/geometry/mesh::VelocityMesh

### 3.2.2 Attributes

For simplicity, attributes of an element are treated the same as children of the element. Consider the example above: name is an attribute of the mesh element. The name of the first mesh element may be accessed by

/geometry/mesh[0]/name  

that is, the name attribute is accessed the same way as a child element called name would be.

Attributes in the options tree must have string type data and have no children. If either of these rules are broken (e.g. via a 3.5.15 call) then the attribute element will be unmarked as an attribute, will be treated as a normal element, and will appear in XML files written out by libspud as XML elements rather than element attributes.

### 3.2.3 Data elements

Data defined in the Spud base language (see 2.2), such as integer_value or real_value, are detected by libspud and stored in "__value" children. e.g, for the following schema:

```
<model_options>
  <real_parent>
    <ref name="real_value"/>
  </real_parent>
</model_options>
```

the data element "real_value" has option key "/real_parent/__value". Alternatively, the data element "real_value" can be accessed directly with option key "/real_parent" - i.e. libspud automatically navigates into "__value" child elements when reading or setting options, if such a child element exists.

Manually creating a "__value" child for an element that already itself contains data will result in the data of the parent element being removed, and a warning message will be sent to standard error.

### 3.3 Language specific features

In some cases the interfaces differ slightly between Fortran, C and C++. This is brought about by differences in the designs of these languages themselves and in particular the difference in the manner in which optional arguments are supported in Fortran on the one hand and C/C++ on the other. The decision has been made to write the interfaces in the manner which seems natural in each language at the cost of consistency between languages rather than enforcing a foreign paradigm on one or all of the interfaces.
3.3.1 Fortran

All of the Fortran procedures as well as the named constants for error codes (3.5.1) and data types (3.6.2) are encapsulated in the spud module.

Where a routine returns an error code, in Fortran this is achieved via the optional stat argument. If stat is not present and an error code other than SPUD_NO_ERROR is returned then execution will halt with an error message.

3.3.2 C

Since C does not itself have any namespacing facility, all exposed symbols have the prefix spud_. Error codes are returned via function return values.

3.3.3 C++

The entire public C++ API of libspud is contained in the Spud namespace. Error codes are returned via function return values.

3.4 Naming conventions

Where a routine returns its main result via an argument (as is the case for a Fortran subroutine, for example), the routine’s name starts with get_. The word key is exclusively used to refer to a lookup key in the options dictionary.

3.5 Procedure interfaces

In each case, the Fortran interface is given first, followed by the C and then C++ interfaces.

3.5.1 Error codes

The following values are return statuses of procedures. In Fortran these are named constants in the spud module while in C and C++ these are the enum types SpudOptionError and Spud::OptionError respectively.

Error values are greater than zero, warnings are negative and SPUD_NO_ERROR has the value 0.
3.5. PROCEDURE INTERFACES

<table>
<thead>
<tr>
<th>Error code</th>
<th>Interpretation</th>
</tr>
</thead>
<tbody>
<tr>
<td>SPUD_NO_ERROR</td>
<td>Successful completion.</td>
</tr>
<tr>
<td>SPUD_KEY_ERROR</td>
<td>The specified option is not present in the dictionary.</td>
</tr>
<tr>
<td>SPUD_TYPE_ERROR</td>
<td>The specified option has a different type from that of the option argument provided.</td>
</tr>
<tr>
<td>SPUD_RANK_ERROR</td>
<td>The specified option has a different rank from that of the option argument provided.</td>
</tr>
<tr>
<td>SPUD_SHAPE_ERROR</td>
<td>The specified option has a different shape from that of the option argument provided.</td>
</tr>
<tr>
<td>SPUD_FILE_ERROR</td>
<td>The specified options file cannot be read or written to as the routine requires.</td>
</tr>
<tr>
<td>SPUD_NEW_KEY_WARNING</td>
<td>The option being inserted is not already in the dictionary.</td>
</tr>
<tr>
<td>SPUDATTR_SET_FAILED_WARNING</td>
<td>The option being set as an attribute can not be set as an attribute.</td>
</tr>
</tbody>
</table>

3.5.2 Data type parameters

The option_type routine returns the following values. In Fortran these are named constants in the `spud` module while in C and C++ these are the enum types `SpudOptionType` and `Spud::OptionType` respectively.

<table>
<thead>
<tr>
<th>Fortran</th>
<th>C/C++</th>
</tr>
</thead>
<tbody>
<tr>
<td>SPUD_REAL</td>
<td>SPUD_DOUBLE</td>
</tr>
<tr>
<td>SPUD_INTEGER</td>
<td>SPUD_INT</td>
</tr>
<tr>
<td>SPUD_NONE</td>
<td>SPUD_NONE</td>
</tr>
<tr>
<td>SPUD_CHARACTER</td>
<td>SPUD_STRING</td>
</tr>
</tbody>
</table>

3.5.3 clear_options

```fortran
subroutine clear_options()
end subroutine clear_options
```

```c
void spud_clear_options()
```

```c
void Spud::clear_options();
```

Clears the entire options tree.

3.5.4 load_options

```c
function load_options(filename, stat)
    character(len=*) :: filename
    integer, optional, intent(out) :: stat
end function load_options
```

```c
int spud_load_options(const char* key, const int key_len)
```

```c
OptionError Spud::load_options(const std::string& filename)
```

Reads the XML file `filename` into the options tree.

Returns error code `SPUD_FILE_ERROR` if the file does not exist or cannot be read.
3.5.5  write_options

```fortran
subroutine write_options(filename, stat)
  character(len=*) intent(in) :: filename
  integer, optional, intent(out) :: stat

int spud_write_options(const char* filename, const int filename_len)
```

OptionError write_options(const std::string& filename)

Writes the options tree out to the XML file filename.
Returns error code SPUD_FILE_ERROR if the file does not exist or cannot be written.

3.5.6  get_child_name

```fortran
subroutine get_child_name(key, index, child_name)
  character(len=*) intent(in) :: key
  integer intent(in) :: index
  character(len=*) intent(out) :: child_name

int spud_get_child_name(const char* key, const int key_len, char* child_name, const int child_name_len)
```

Spud::OptionError Spud::get_child_name(const std::string& key, const unsigned& index, std::string& child_name)

Retrieves the name of the ith child of key. This is mostly useful for debugging input files.
Returns error code SPUD_KEY_ERROR if the supplied key does not exist in the options tree.

3.5.7  get_number_of_children

```fortran
function number_of_children(key, child_count)
  integer :: number_of_children
  character(len=*) intent(in) :: key
  integer, intent(out) :: child_count
  integer, optional, intent(out) :: stat

int spud_get_number_of_children(const char* key, const int key_len, int* child_count)
```

int Spud::get_number_of_children(const std::string& key, int& child_count)

On return, child_count the number of children under key. This is mainly of use for debugging input files.
Returns the error code SPUD_KEY_ERROR if the specified key does not exist in the options tree.
3.5.8 option_count

```
function option_count(key)
  integer :: option_count
  character(len=*) , intent(in) :: key

int spud_option_count(const char* key, const int key_len)

int Spud::option_count(const std::string& key)
```

Returns the number of options which match `key`. Searches all possible paths matching the given key. For example, for the following XML file:

```
<model_options>
  <scalar_field name="pressure">
    <solver>
      ...
    </solver>
  </scalar_field>
  <scalar_field name="temperature">
    <solver>
      ...
    </solver>
  </scalar_field>
</model_options>
```

in the following Fortran code:

```
n_child = option_count("/scalar_field/solver")
```

*n_child* is assigned the value 2.

This routine is useful where an option can occur any number of times (for example a simulation may allow for any number of fields to be specified).

Returns 0 if *key* is not present in the dictionary.

3.5.9 have_option

```
function have_option(key)
  logical :: have_option
  character(len=*) , intent(in) :: key

int spud_have_option(const char* key, const int key_len)

logical_t Spud::have_option(const std::string& key)
```

Returns true if *key* is present in the options dictionary, and false otherwise. This is useful for determining whether optional options have been set and for determining which of a choice of options has been selected.
3.5.10 option_type

```cpp
function option_type(key, stat) result (type)
  integer :: type
  character(len=*) , intent(in) :: key
  integer, optional, intent(out) :: stat
end function option_type
```

```cpp
int spud_get_option_type(const char* key, const int key_len, int* type)
```

Spud::OptionError Spud::get_option_type(const std::string& key, Spud::OptionType& type)

Returns the type of the option specified by `key`. The type will be returned as one of the named constants in 3.6.2.

Returns error code SPUD_KEY_ERROR if the supplied key does not exist in the options tree.

3.5.11 option_rank

```cpp
function option_rank(key, stat) result (rank)
  integer :: rank
  character(len=*) , intent(in) :: key
  integer, optional, intent(out) :: stat
end function option_rank
```

```cpp
int spud_get_option_rank(const char* key, const int key_len, int* rank)
```

Spud::OptionError Spud::get_option_rank(const std::string& key, int& rank)

Returns the rank of the option specified by `key`. The rank returned will be 0 (for a scalar), 1 (for a vector) or 2 (a rank 2 tensor, or matrix).

Returns error code SPUD_KEY_ERROR if the supplied key does not exist in the options tree.

3.5.12 option_shape

```cpp
function option_shape(key, stat) result (lshape)
  integer, dimension(2) :: lshape
  character(len=*) , intent(in) :: key
  integer, optional, intent(out) :: stat
end function option_shape
```

```cpp
int spud_get_option_shape(const char* key, const int key_len, int* shape)
```

Spud::OptionError Spud::get_option_shape(const std::string& key, std::vector<int>& shape)

Returns the shape of the option specified by `key`. The shape is always a 2-vector. If the option in question is rank 1 then the second component will be -1, if the option is rank 0 (a scalar) then both entries will be -1.

Returns error code SPUD_KEY_ERROR if the supplied key does not exist in the options tree.
### 3.5. PROCEDURE INTERFACES

#### 3.5.13 get_option

```fortran
subroutine get_option(key, val, stat, default)
    character(len=*)    :: key
    option_type,      intent(in) :: val
    integer,     optional, intent(out) :: stat
    option_type,     optional, intent(in) :: default
end subroutine get_option
```

```c
int spud_get_option(const char* key, const int key_len, void* val)
```

This is the main method for retrieving option values from the options dictionary. For Fortran and C++ `option_type` can be any of the following values:

<table>
<thead>
<tr>
<th>Fortran type</th>
<th>C++ type</th>
</tr>
</thead>
<tbody>
<tr>
<td>double precision</td>
<td>double&amp;</td>
</tr>
<tr>
<td>double precision, dimension(:)</td>
<td>std::vector&lt;double&gt;&amp;</td>
</tr>
<tr>
<td>double precision, dimension(:,:,1)</td>
<td>std::vector&lt; std::vector&lt;double&gt; &gt; &amp;</td>
</tr>
<tr>
<td>integer</td>
<td>int&amp;</td>
</tr>
<tr>
<td>integer, dimension(,:)</td>
<td>std::vector&lt;int&gt;&amp;</td>
</tr>
<tr>
<td>integer, dimension(:,:,1)</td>
<td>std::vector&lt; std::vector&lt;int&gt; &gt; &amp;</td>
</tr>
<tr>
<td>character(len=*)</td>
<td>std::string&amp;</td>
</tr>
</tbody>
</table>

In Fortran, single precision interfaces are also provided in each of the above cases. However, these values will be stored in the options dictionary in double precision. In every case the type and shape of the argument must match that of the option in the dictionary. In C the returned argument is always a `void` pointer and it is the responsibility of the user to match the size and type correctly.

This routine can return the following error codes:

- If `key` matches an option but the shape, rank or type fails to match, appropriate error code will be set (see 3.5.1).
- If `key` fails to match but `default` is present, `option` is set to the value of `default`.
- If `key` fails to match and `default` is not present, the error code will be set to `SPUD_KEY_ERROR`.

#### 3.5.14 add_option

```fortran
subroutine add_option(key, stat)
    character(len=*) :: key
    integer,     optional, intent(out) :: stat
end subroutine add_option
```

```c
int spud_add_option(const char* key, const int key_len)
```

Creates a new option at the supplied key. If the option does not currently exist, creates the option (with data type `SPUD_NONE`) and returns error code `SPUD_NEW_KEY_WARNING`. 
3.5.15 set_option

```fortran
subroutine set_option(key, val, stat)
    character(len=*) , intent(in) :: key
    option_type , intent(in or inout) :: val
    integer , optional , intent(out) :: stat

int spud_set_option(const char* key, const int key_len, const void* val, const int type, const int rank, const int* shape)
```

Method for setting options in the options tree. The `option_type` can be any of the types listed above in 3.5.13.

This routine can return the following error codes:

- If `key` matches an option but the shape, rank or type fails to match currently existing option, returns an appropriate error code (see 3.5.1).
- If `key` fails to match, creates a new option at the supplied key, sets the option to `val` and returns error code `SPUD_NEW_KEY_WARNING`.

3.5.16 set_option_attribute

```fortran
subroutine set_option_attribute(key, val, stat)
    character(len=*) , intent(in) :: key
    character(len=*) , intent(in) :: val
    integer , optional , intent(out) :: stat

int int spud_set_option_attribute(const char* key, const int key_len, const char* val, const int val_len)
```

As `set_option` (see 3.5.15), but additionally attempts to mark the option at the specified key as an attribute. Note that `set_option_attribute` accepts only string data for `val`.

This routine can return the following error codes:

- If `key` matches an option but the shape, rank or type fails to match currently existing option, returns an appropriate error code (see 3.5.1).
- If `key` fails to match, creates a new option at the supplied key, sets the option to `val` and returns error code `SPUD_NEW_KEY_WARNING`.
- If `key` matches an option, but the existing option has children, sets the option to `val` and returns error code `SPUD_ATTR_SET_FAILED_WARNING`. 
3.5.17 delete_option

```plaintext
subroutine delete_option(key, stat)
    character(len=*), intent(in) :: key
    integer, optional, intent(out) :: stat
```

```plaintext
int spud_delete_option(const char* key, const int key_len)
```

Spud::OptionError Spud::delete_option(const std::string& key)

Deletes the option at the specified key.
Returns error code SPUD_KEY_ERROR if the supplied key does not exist in the options tree.

3.5.18 move_option

```plaintext
subroutine move_option(key1, key2, stat)
    character(len=*), intent(in) :: key1
    character(len=*), intent(in) :: key2
    integer, optional, intent(out) :: stat
```

```plaintext
int spud_move_option(const char* key1, const int key1_len, const char* key2, const int key2_len)
```

Spud::OptionError Spud::move_option(const std::string& key1, const std::string& key2)

Moves the entire options tree and all its children from key1 to key2.

3.5.19 copy_option

```plaintext
subroutine copy_option(key1, key2, stat)
    character(len=*), intent(in) :: key1
    character(len=*), intent(in) :: key2
    integer, optional, intent(out) :: stat
```

```plaintext
int spud_copy_option(const char* key1, const int key1_len, const char* key2, const int key2_len)
```

Spud::OptionError Spud::copy_option(const std::string& key1, const std::string& key2)

Copies the entire options tree and all its children from key1 to key2.

3.5.20 print_options

```plaintext
subroutine print_options()
```

```plaintext
void spud_print_options()
```

```plaintext
void Spud::print_options()
```

Prints the entire options tree to standard output. Useful for debugging.
3.6 Python binding for libspud

libspud also offers bindings for the Python programming language. Users can use Python for accessing the options specified in a Spud XML file. (This is done by the libspud.c module. The module is written in C using the header file Python.h and spud.h. It provides a Python interface to libspud; so that users could use Python codes to access the C codes in libspud. The module takes in Python arguments, converts them into C arguments and then call the corresponding C functions with the converted C arguments.)

3.6.1 Errors

Python binding converts spud errors into exceptions, and that these exceptions match those listed in 3.5.2:
SpudError;
SpudTypeError;
SpudKeyError;
SpudFileError;
SpudNewKeyWarning;
SpudAttrSetFailedWarning;
SpudShapeError;
SpudRankError;

3.6.2 Data type parameters

The option_type routine returns the following values. In Fortran these are named constants in the spud module while in C and C++ these are the enum types SpudOptionType and Spud::OptionType respectively.

<table>
<thead>
<tr>
<th>Fortran</th>
<th>C/C++</th>
<th>Python</th>
</tr>
</thead>
<tbody>
<tr>
<td>SPUD_REAL</td>
<td>SPUD_DOUBLE</td>
<td>float</td>
</tr>
<tr>
<td>SPUD_INTEGER</td>
<td>SPUD_INT</td>
<td>int</td>
</tr>
<tr>
<td>SPUD_NONE</td>
<td>SPUD_NONE</td>
<td>None</td>
</tr>
<tr>
<td>SPUD_CHARACTER</td>
<td>SPUD_STRING</td>
<td>str</td>
</tr>
</tbody>
</table>

3.6.3 clear_options

```python
def clear_options()
    return None
```

This function takes no arguments and returns None. Clears the entire options tree.

3.6.4 load_options

```python
def load_options(string filename)
    return None
```

This function takes the XML filename in the form of a Python string and raises SpudFileError if file cannot be read or does not exist. Otherwise, it reads the file into the options tree, and then returns None.
3.6.5 write_options

```python
def write_options(string filename)
    return None
```

This function takes the XML filename in the form of a Python string and raises SpudFileError if file
cannot be written or does not exist. Otherwise, it writes the options tree to the file, and then returns
None.

3.6.6 get_child_name

```python
def get_child_name(string key, int index)
    return string
```

This function takes the key in the form of a Python string, and an integer index. It raises SpudKey-
Error if supplied key does not exist in the options tree. Otherwise, it retrieves the childname of the
indexth of key, and then returns the childname as Python string.

3.6.7 get_number_of_children

```python
def get_number_of_children(string key)
    return int
```

This function takes the key in the form of a Python string. It raises SpudKeyError if supplied key
does not exist in the options tree. Otherwise, it returns the number of children of the key as Python integer.

3.6.8 option_count

```python
def option_count(string key)
    return int
```

This function takes the key in the form of a Python string. It returns the number of options which
match the key as Python integer. It returns 0 if key is not present in the dictionary.

3.6.9 have_option

```python
def have_option(string key)
    return True or False
```

This function takes the key in the form of a Python string. It returns True if the key is present in the
options dictionary, False otherwise.

3.6.10 get_option_type

```python
def get_option_type(string key)
    return PyObject_Type
```

This function takes the key in the form of a Python string. It raises SpudKeyError if the supplied key
does not exist in the options tree. It returns the type of the key as one of the Python object types in
3.6.2.
3.6.11 get_option_rank

```python
def get_option_rank(string key):
    return int
```

This function takes the key in the form of a Python string. It raises SpudKeyError if the supplied key does not exist in the options tree. It returns the rank of the key as Python ints. 0 for scalar, 1 for vector, 2 for tensor or matrix.

3.6.12 get_option_shape

```python
def get_option_shape(string key):
    return (int, int)
```

This function takes the key in the form of a Python string. It raises SpudKeyError if the supplied key does not exist in the options tree. It returns the shape of the key as Python two-tuple. If the option in question is rank 1 then the second component will be -1, if the option is rank 0 (a scalar) then both entries will be -1.

3.6.13 get_option

```python
def get_option(string key):
    return optionvalue
```

This function takes the key in the form of a Python string. If key matches an option but the shape, rank or type fails to match, appropriate error code will be set (see 3.6.1). If key fails to match but default is present, option is set to the value of default. If key fails to match and default is not present, the error code will be set to SpudKeyError. It returns the value of the option, the value could be of any type.

3.6.14 add_option

```python
def add_option(string key):
    return None
```

This function takes the key in the form of a Python string. It creates a new option at the supplied key. If the option does not currently exist, creates the option (with data type SPUD_NONE) and returns error code SpudNewKeyWarning.

3.6.15 set_option

```python
def set_option(string key, valuetype value):
    return None
```

This function takes the key in the form of a Python string, and the value to be set. Value could be of any type listed in 3.6.2. If key matches an option but the shape, rank or type fails to match currently existing option, returns an appropriate error code (see 3.6.1). If key fails to match, creates a new option at the supplied key, sets the option to value and returns error code SpudNewKeyWarning. This function is for setting options in the options tree.
3.6.16  set_option_attribute

```python
def set_option_attribute(string key, valuetype value)
return None
```

This function takes the key in the form of a Python string, and the value to be set. Value could be of any type listed in 3.6.2. If key matches an option but the shape, rank or type fails to match currently existing option, returns an appropriate error code (see 3.6.1). If key fails to match, creates a new option at the supplied key, sets the option to value and returns error code SpudNewKeyWarning. If key matches an option, but the existing option has children, sets the option to val and returns error code SpudAttrSetFailedWarning. This function is for setting options in the options tree, but additionally attempts to mark the option at the key as an attribute.

3.6.17  delete_option

```python
def delete_option(string key)
return None
```

This function takes the key in the form of a Python string. It raises SpudKeyError if the supplied key does not exist in the options tree. This function deletes the option in the options tree.

3.6.18  print_options

```python
def print_options()
return None
```

This function takes no arguments. It prints the entire options tree to standard output.
Chapter 4

Diamond

4.1 Installation

Diamond depends on Python (version 2.3 or greater), PyGTK, the 4Suite XML library, and the lxml library. All of these dependencies are available in the Debian/Ubuntu repositories with the following command:

```
apt-get install python-gtk2 python-lxml python-4suite-xml
```

Windows versions of these packages are available for download on their respective websites.

4.2 Configuration files

In accordance with normal Unix practice, system wide configuration for diamond is stored in the `/etc/diamond` directory while per-user configuration is stored in a `.diamond` directory in the user's home directory.

4.2.1 Colour

Diamond diff view uses colour to display differences between documents. These colours are configured by a text file in the diamond directory called `settings` with the following contents:

```
[colour]
normal = black
insert = green
delete = red
update = blue
subupdate = cornflowerblue
diffadd = lightgreen
diffsub = indianred
```

All colours are optional and will be filled in to the above default values if not given. The colour are specified with X11 colour names, see here.

4.2.2 Schemas

Diamond needs to know which Spud schemas are installed and available on the current system. This is specified in the `schemata` subdirectory of the `/etc/diamond` and `~/.diamond` directories.
The file names in the `schemata` directory give the filename extension associated with a particular problem description language. The content of the file is two or more lines. The first line is the name of the problem description language, the remaining lines are key value pairs (key = value) of alias names and the path of the XML syntax (.rng) version of the corresponding schema. A line with no "key = " part will be interpreted as "default = ".

For example, the Fluidity package has a problem description language called the Fluidity Markup Language which uses the file extension `.flml`. When installed on a system by the sysadmin, Fluidity might create the file `/etc/diamond/flml` with the following contents:

```
Fluidity Markup Language
/usr/share/fluidity/fluidity_options.rng
```

An individual user `jrluser` might have the current version of the Fluidity svn tree checked out in their home directory and would need to point diamond at the (possibly updated) schema in their source tree. `jrluser` would then create the file `/home/jrluser/.diamond/schemata/flml` which would contain:

```
Fluidity Markup Language
/home/jrluser/fluidity/schemas/fluidity_options.rng
```

Now Diamond will pick up the version of the schema in `jrluser`'s svn tree rather than the version the sysadmin installed. Alternatively they could just add an alias to the existing `/home/jrluser/.diamond/schemata/flml`:

```
Fluidity Markup Language
/usr/share/fluidity/fluidity_options.rng
jrl = /home/jrluser/fluidity/schemas/fluidity_options.rng
```

It is also possible to specify a URL over HTTP for the location of the schema. For example:

```
Fluidity Markup Language
http://amcg.ese.ic.ac.uk/svn/fluidity/trunk/tools/fluidity_options.rng
```

This is to facilitate centralised deployments.

### 4.3 Starting Diamond

Diamond can be started in several ways.

When executed as

```
diamond
```

Diamond will offer the user the choice of which registered schema to use. If only one schema is registered, then it will use that by default. Diamond will open a blank document of the language specified by the schema to be edited.

When executed as

```
diamond -s /path/to/schema.rng
```

Diamond will open a blank document using the schema specified on the command line.

When executed as

```
diamond filename.suffix
```

Diamond will inspect the registered schemas for the suffix specified and use that schema.
4.4 Using Diamond

Diamond provides three views.

**Main view** Is how Diamond starts up.

**Slice view** Shows same type elements together.

**Diff view** Shows the differences between the open document and another.

4.4.1 Main view

The main view shows the tree structure of the document on the left hand side and data and documentation for the currently selected element on the right hand side. The treeview can be traversed with either the mouse by clicking to open, close, add and destroy elements or with the keyboard, using the arrows keys, enter and delete. Elements can be copied (puts the XML representation onto the clipboard) or XML can be pasted into an element. Finally elements of the same type can be grouped together, this will bring all elements of the selected type to the top level and hide other elements. Ungroup will then return the view to normal.

4.4.2 Slice view

Slice view is opened by right clicking an element and selecting Slice or selecting an element and then selecting Slice in the Edit menu. The slice view shows a list of a given type of element. Each item shows the path, data and attributes for that element.

4.4.3 Diff view

To open diff view select Diff or Diff against last save in the Tools menu. The diff view shows the differences between the currently open document (understood to be the newer version) and a user selected document (understood to be the older version). The diff view does NOT understand some conventions used in the main view such as hiding certain elements (for example real_value or comment). The colours used in the diff view can be set in the settings file see 4.2.1.

4.4.4 Dynamic validation

Diamond uses the schema to guide the editing of valid documents that the schema permits. When a blank document is opened, information necessary to make a valid document is missing and the document is thus invalid\(^1\). The invalidity of the document is reflected in the colouration of the root node: valid nodes are coloured in black, while invalid nodes are coloured in blue. As invalid nodes have their attributes and data specified, their validity is dynamically updated and they are coloured appropriately. The document as a whole is valid if and only if the root node is coloured black.

4.4.5 Finding unused schema elements

Diamond has a built in tool to test multiple document files against one schema to see what parts of the schema are not used. In the Tools menu select Find schema usage, it will prompt for an input directory. It will find every file with a matching suffix (.flml for Fluidity Markup Language) in the directory tree and check the schema against them.

\(^1\)This is true for all but a trivial schema which permits only one document.
Chapter 5

Miscellaneous tools

5.1 Spud-set

Spud-set is a short Python script which enables users to make small modifications to the values of options in Spud options files on the command line. This is particularly useful where users wish to script a number of model runs exploring different values of one or more parameters.

The syntax of spud-set is:

```
spud-set filename xpath new_value
```

where:

- **filename** is the name of the options file which is to be modified.
- **xpath** is the xpath of the option to be modified (see below).
- **new_value** is the new value which the option should take.

5.1.1 xpath

An xpath is a language which provides a mechanism for addressing parts of an xml file. It uses paths similar in some ways to those used to retrieve options in libspud. A full description of xpath syntax is to be found in the World Wide Web Consortium XPath Recommendation. However, users of Spud will usually find it much easier to use the xpahs generated by Diamond. The xpath for any option is shown at the bottom of the Diamond window when that option is selected and can be copied to the clipboard using the “copy spud path” option from the edit menu.
